Understanding the Execution of Analytics Queries & Applications

MAS DSE 201

SQL as declarative programming

- SQL is a **declarative** programming language:
 - The developer's / analyst's query only describes what result she wants from the database
 - The developer does not describe the algorithm that the database will use in order to compute the result
- The database's optimizer automatically decides what is the most performant algorithm that computes the result of your SQL query
- "Declarative" and "automatic" have been the reason for the success and ubiquitous presence of database systems behind applications
 - Imagine trying to come up yourself with the algorithms that efficiently execute complex queries. (Not easy.)

What do you have to do to increase the performance of your db-backed app?

- Does declarative programming mean the developer does not have to think about performance?
 - After all, the database will automatically select the most performant algorithms for the developer's SQL queries
- No, challenging cases force the A+ SQL developer / analyst to think and make choices, because...
 - Developer decides which indices to build
 - Database may miss the best plan: Developer has to understand what plan was chosen and work around

Diagnostics

- You need to understand a few things about the performance of your query:
- 1. Will it benefit from indices? If yes, which are the useful indices?
- 2. Has the database chosen a hugely suboptimal plan?
- 3. How can I hack it towards the efficient way?

What are the first principles?

Hadoop is just a file system and how you process the data is on you How would I manually optimize the query by writing algorithms from scratch?

Boosting performance with indices (a short conceptual summary)

How/when does an index help? Running selection queries without an index

Consider a table R with *n* tuples and the selection query

SELECT *
FROM R
WHERE R.A = ?

In the absence of an index the Big-O cost of evaluating an instance of this query is O(n) because the database will need to access the n tuples and check the condition

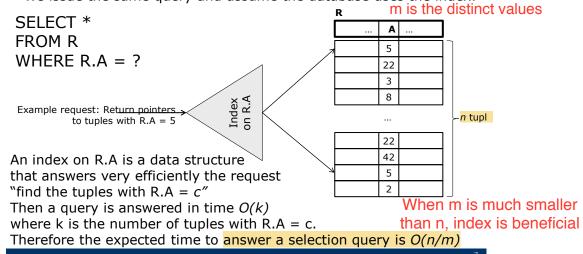

R.A = cprovided value>

R		
	Α	
	5	
	22	
	3	
	8	
		_n tuples
	22	
	42	
	5	
	2	

How/when does an index help? Running selection queries with an index

Consider a table R with *n* tuples, an index on R.A and assume that R.A has *m* distinct values.

We issue the same query and assume the database uses the index.

The mechanics of indices: How to create an index

How to create an index on R.A?

After you have created table **R**, issue command **CREATE INDEX myIndexOnRA ON R(A)**

How to remove the index you previously created?

DROP INDEX myIndexOnRA

Exercise: Create and then drop an index on Students.first_name of the enrollment example

After you have created table **students**, issue command **CREATE INDEX students_first_name ON students(first_name)**

DROP INDEX students_first_name

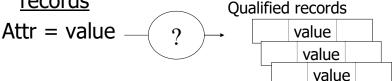

Primary keys get an index automatically

The mechanics of indices: How to use an index in a query

- *evaluate the rate at which the data will be queried and accessed, versus the rate of the changing of the data in the database
- You do **not** have to change your SQL queries in order to direct the database to use (or not use) the indices you created.
 - All you need to do is to create the index! That's easy...
- The database will decide automatically whether to use (or not use) a created index to answer your query.
- It is possible that you create an index x but the database may not use it if it judges that there is a better plan (algorithm) for answering your query, without using the index x.

Indexing will help any query step when the problem is...

Given condition on attribute find qualified records Ouglified records

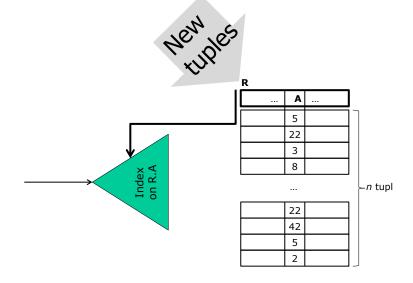

Condition may also be

- Attr>value
- Attr>=value

Indexing

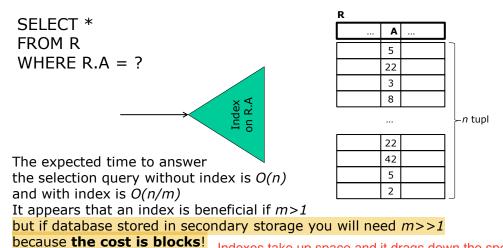

- Data Stuctures used for quickly locating tuples that meet a specific type of condition
 - Equality condition: find Movie tuples where Director=X
 - Other conditions possible, eg, range conditions: find Employee tuples where Salary>40 AND Salary<50
- Many types of indexes. Evaluate them on
 - Access time
 - Insertion time
 - Deletion time
 - Space needed (esp. as it effects access time and or ability to fit in memory)

Should I build an index? In the presence of updates, the benefit of an index has to take maintenance cost into account

In OLAP it seems beneficial to create an index on R.A whenever m>1

Recall: Table R with *n* tuples, an index on R.A and assume that R.A has *m* distinct values

If tuples are small, it may not help because you have to retrieve 4kb at a time. It will be a useless index. You spend time utilizing the index to do pointers and the db won't use it. Indexes take up space and it drags down the speed of building the db every night. The index may not be worth it. Rethink if the architecture is in any active/active active/passive or replicated environments?

Block based medium - when the system asks the SSD to fetch a tuple, it fetches an entire block of the SSD. It comes out with a block of 4kb.

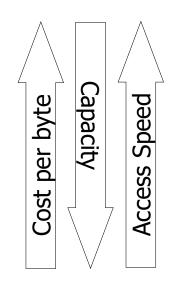

To Index or Not to Index

- Which queries can use indices and how?
- What will they do without an index?
 - Some surprisingly efficient algorithms that do not use indices

Understanding Storage and Memory

Memory Hierarchy

- Cache memory
 - On-chip and L2
 - Increasingly important
- RAM (controlled by db system)
 - Addressable space includes virtual memory but DB systems avoid it
- SSDs
 - Block-based storage
- Disk
 - Block
 - Preference to sequential access
- Tertiary storage for archiving
 - Tapes, jukeboxes, DVDs
 - Does not matter any more

Non-Volatile Storage is important to OLTP even when RAM is large

- Persistence important for transaction atomicity and durability
- Even if database fits in main memory changes have to be written in nonvolatile storage
- Hard disk
- RAM disks w/ battery
- Flash memory

17

Peculiarities of storage mediums affect algorithm choice

- Block-based access:
 - Access performance: How many blocks were accessed
 - How many objects
 - Flash is different on reading Vs writing Writing is slower
- Clustering for sequential access:
 - Accessing consecutive blocks costs less on disk-based systems
- We will only consider the effects of block access
 Sequential Access faster than random access

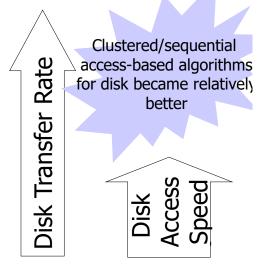

Moore's Law: Different Rates of Improvement Lead to Algorithm & System Reconsiderations

- Processor speed
- Main memory bit/\$
- Disk bit/\$
- RAM access speed
- Disk access speed
- Disk transfer rate

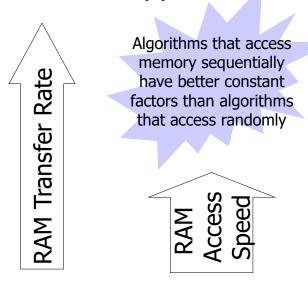

They don't get better at the same rate.

Last 20 years of hard drives, they've been improving transfer rate, and they are improving access speed to reach a block.

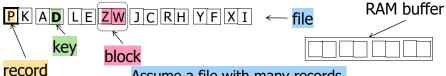

But they've been improving at different rates. They double every two years.

Moore's Law: Same Phenomenon Applies to RAM

2-Phase Merge Sort: An algorithm tuned for blocks (and sequential access)

Fastest algorithm to sort an array - QuickSort the number of steps it takes to sort n items in an array = n*logn

If the dominant cost is accessing the blocks, you want to minimize block access, the 2 phase merge sort scans the file just twice.

Assume a file with many records.

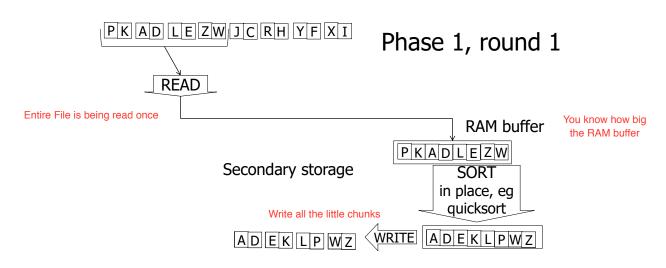

Each record has a key and other data. For ppt brevity, the slide shows only the key of each record and not its data. Assume each block has 2 records.

Assume RAM buffer fits 4 blocks (8 records) In practice, expect many more records

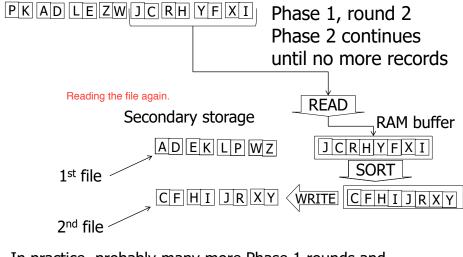

per block and many more records fitting in buffer.

Problem: Sort the records according to the key. **Morale:** What you learnt in algorithms and data structures is not always the best when we consider block-based storage

2-Phase Merge Sort

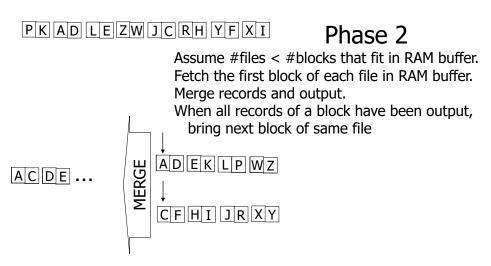

2-Phase Merge Sort

In practice, probably many more Phase 1 rounds and many respective output files

2-Phase Merge Sort

23

Improvement: Bring max number of blocks in memory.

2-Phase Merge Sort: Most files can be sorted in just 2 passes!

Assume

- M bytes of RAM buffer (eg, 8GB)
- *B* bytes per block (eg, 64KB for disk, 4KB for SSD) Calculation:
- The assumption of Phase 2 holds when #files < M/B

RAM buffer/ Size of Block

- => there can be up to M/B Phase 1 rounds
- Each round can process up to M bytes of input data
- => 2-Phase Merge Sort can sort M^2/B bytes - eq (8GB)²/64KB = (2³³B)² / 2¹⁶B= 2⁵⁰B = 1PB

The amount you can sort increases quadratically with memory

We learned 3 things: How to sort a massive file How databases sort

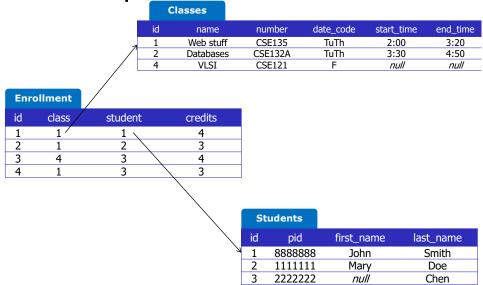

How an algorithm for secondary storage is used versus primary storage

Horizontal placement of SQL data in blocks

Relations:

- Pack as many tuples per block
 - improves scan time
- Do not reclaim deleted records
- Utilize overflow records if relation must be sorted on primary key
- A novel generation of databases features column storage
 - to be discussed late in class

Sample relational database

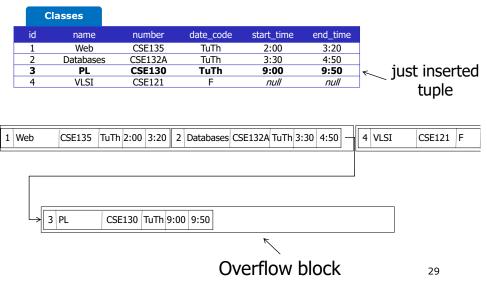

Pack maximum #records per block

(Classes				
id	name	number	date_code	start_time	end_time
1	Web	CSE135	TuTh	2:00	3:20
2	Databases	CSE132A	TuTh	3:30	4:50
4	VLSI	CSE121	F	null	null

"pack" each block with maximum # records

Utilize overflow blocks for insertions with "out of order" primary keys

... back to Indices, with secondary storage in mind

- Conventional indexes
 - As a thought experiment
- B-trees
 - The workhorse of most db systems
- Hashing schemes
 - Briefly covered

primary storage hashing schemes vs. secondary storage Evolving dataset vs. fixed dataset

- Bitmaps
 - An analytics favorite

Terms and Distinctions

Primary index

 the index on the attribute (a.k.a. search key) that determines the sequencing of the table

Secondary index

 index on any other attribute

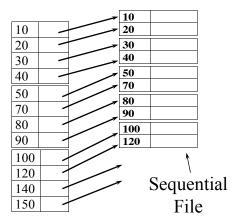

Dense index

 every value of the indexed attribute appears in the index

Sparse index

 many values do not appear

A Dense Primary Index

Dense and Sparse Primary

Indexes

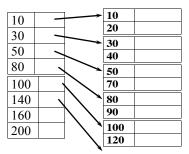

When you want to minimize block access

Dense Primary Index

			10	
10		2	20	
20			30	
30			40	
30 40			50	
50		_	70	
50		E	30	
50 70	_1.		90	
80			100	ĺ
90			120	
100		//-		
120				
140				
150		-		

- + can tell if a value exists without accessing file (consider projection)
- + better access to overflow records

Sparse Primary Index

Find the index record with largest value that is less or equal to the value we are looking.

+ less index space

more + and - in a while

http://en.wikipedia.org/wiki/Database_index#Sparse_index
However, technically, the GIN (aka inverted index) is a form of sparse index that is
available in PostgreSQL. See: http://www.postgresql.org/docs/9.3/static/gin-intro.html

Sparse vs. Dense Tradeoff

- Sparse: Less index space per record can keep more of index in memory
- <u>Dense:</u> Can tell if any record exists without accessing file

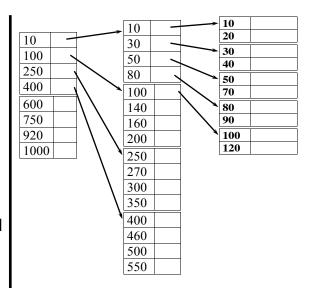

(Later:

- sparse better for insertions
- dense needed for secondary indexes)

33

Multi-Level Indexes

- Treat the index as a file and build an index on it
- "Two levels are usually sufficient.
 More than three levels are rare."
- Q: Can we build a dense second level index for a dense index?

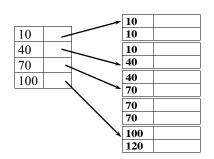

Only really makes sense for the secondary index to be a sparse index

A Note on Pointers

- Record pointers consist of block pointer and position of record in the block
- Using the block pointer only, saves space at no extra accesses cost
- But a block pointer cannot serve as record identifier

Representation of Duplicate Values in Primary Indexes

 Index may point to first instance of each value only

Deletion from Dense Index

Delete 40, 80

- Deletion from dense primary index file with no duplicate values is handled in the same way with deletion from a sequential file
- Q: What about deletion from dense primary index with duplicates

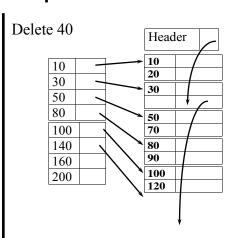

Header

120

Lists of available entries

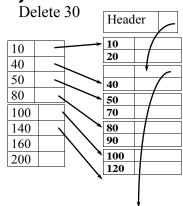

Deletion from Sparse Index

 if the deleted entry does not appear in the index do nothing

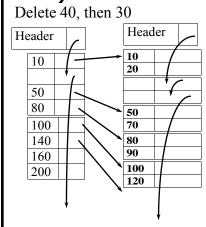

Deletion from Sparse Index (cont'd)

- if the deleted entry does not appear in the index do nothing
- if the deleted entry appears in the index replace it with the next search-key value
 - comment: we could leave the deleted value in the index assuming that no part of the system may assume it still exists without checking the block

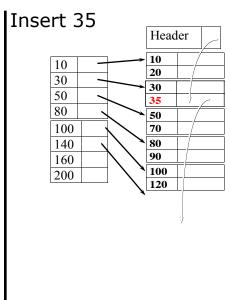

Deletion from Sparse Index (cont'd)

- if the deleted entry does not appear in the index do nothing
- if the deleted entry appears in the index replace it with the next search-key value
- unless the next search key value has its own index entry. In this case delete the entry

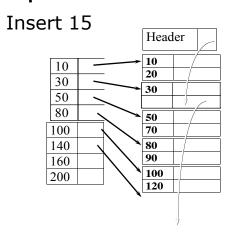

Insertion in Sparse Index

 if no new block is created then do nothing

Insertion in Sparse Index

- if no new block is created then do nothing
- else create overflow record
 - Reorganize periodically
 - Could we claim space of next block?
 - How often do we reorganize and how much expensive it is?
 - B-trees offer convincing answers

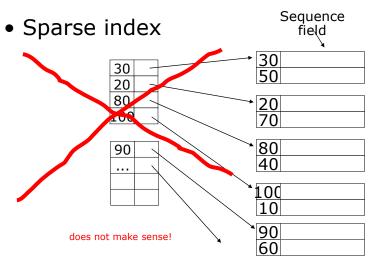

Secondary indexes

File not sorted on secondary search key

30 40	
40	

46

<u>Duplicate values & secondary indexes</u>

one option...

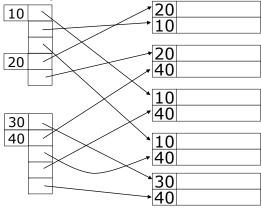

47

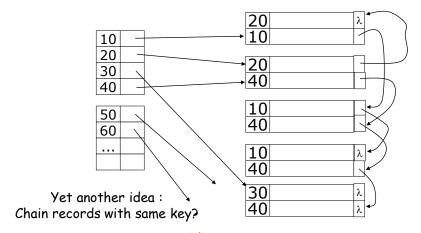

<u>Duplicate values & secondary indexes</u>

nother option: lists of pointers

Problem: variable size records in index!

<u>Duplicate values & secondary indexes</u>

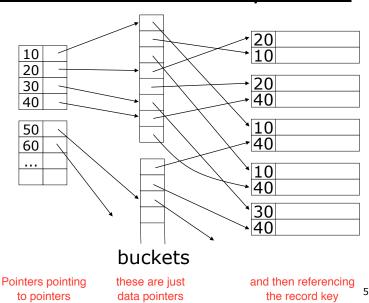

Problems:

- · Need to add fields to records, messes up maintenance
 - Need to follow chain to know records

49

<u>Duplicate values & secondary indexes</u>

Why "bucket" + record pointers is useful

- Enables the processing of queries working with pointers only.
 - Very common technique in Information Retrieval

<u>Indexes</u> Records

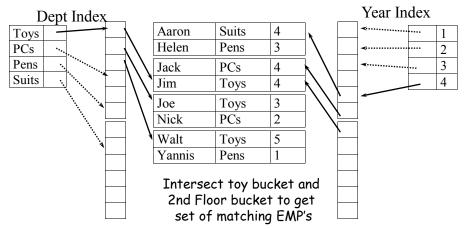

Name: primary EMP (name,dept,year,...)

Dept: secondary Year: secondary

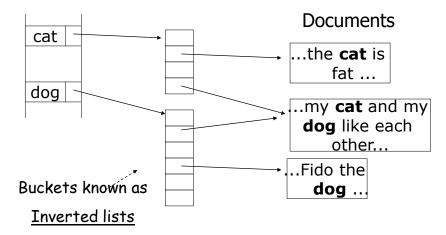

51

Advantage of Buckets: Process Queries Using Pointers Only

Find employees of the Toys dept with 4 years in the company SELECT Name FROM Employee WHERE Dept="Toys" AND Year=4

This idea used in text information retrieval

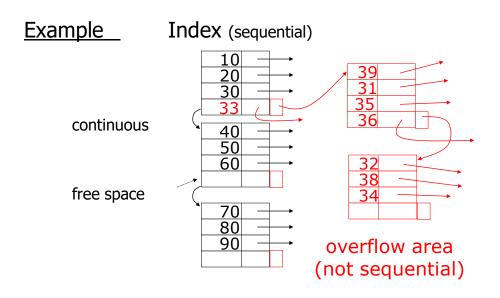

53

Summary of Indexing So Far

- Basic topics in conventional indexes
 - multiple levels
 - sparse/dense
 - duplicate keys and buckets
 - deletion/insertion similar to sequential files

Bad because we have overflows and maintenance issues in order to find the data

- Advantages
 - simple algorithms
 - index is sequential file
- Disadvantages
 - eventually sequentiality is lost because of overflows, reorganizations are needed

55

Outline:

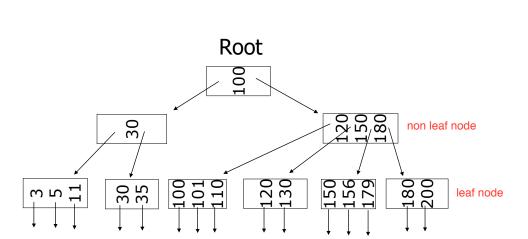

- Conventional indexes
- B-Trees ⇒ NEXT
- Hashing schemes

- NEXT: Another type of index
 - Give up on sequentiality of index
 - Try to get "balance"

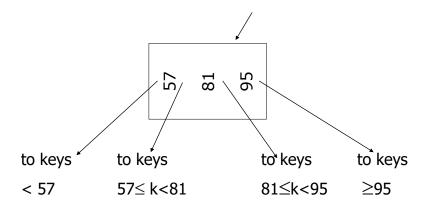

B+Tree Example

57

n=3

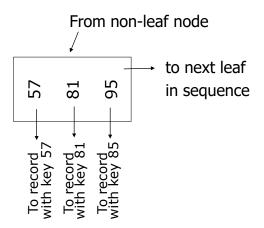

Sample non-leaf

59

Sample leaf node:

In textbook's notation

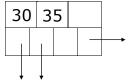

n=3

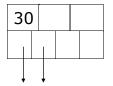

Leaf:

Non-leaf:

61

Size of nodes:

Non-root nodes have to be at least half-full

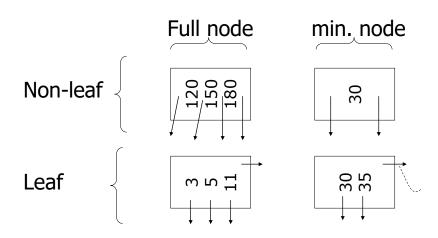

• Use at least

Non-leaf: $\lceil (n+1)/2 \rceil$ pointers

Leaf: $\lfloor (n+1)/2 \rfloor$ pointers to data

63

n=3

<u>B+tree rules</u> tree of order *n*

- (1) All leaves at same lowest level (balanced tree) if every leaf node is the same number of steps to the top
- (2) Pointers in leaves point to records except for "sequence pointer"

Has to be at least half full

65

(3) Number of pointers/keys for B+tree

1	Max ptrs	Max keys	Min ptrs→data	Min keys
Non-leaf (non-root)	n+1	n	「(n+1)/2	「(n+1)/2 - 1
Leaf (non-root)	n+1	n	[(n+1)/2]	[(n+1)/2]
Root	n+1	n	1	1

every node has to be at least half full

Insert into B+tree

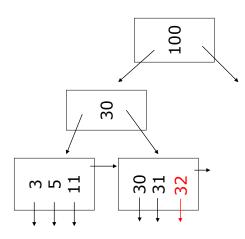

- (a) simple case
 - space available in leaf
- (b) leaf overflow
- (c) non-leaf overflow
- (d) new root

67

(a) Insert key = 32

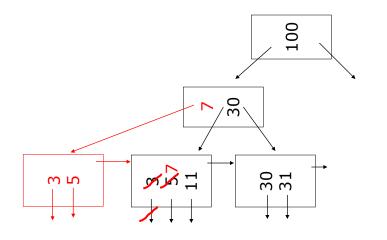

how many I can have in a node

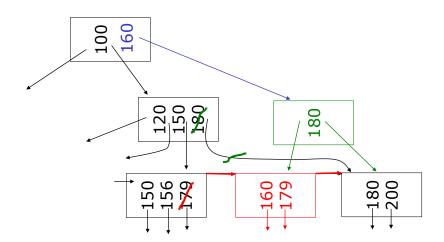

(a) Insert key = 7

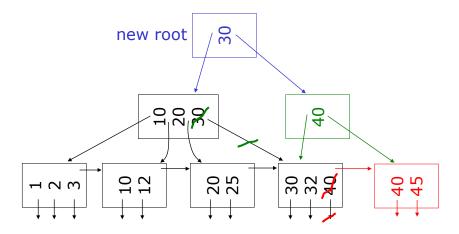

(c) Insert key =
$$160$$

(d) New root, insert 45

71

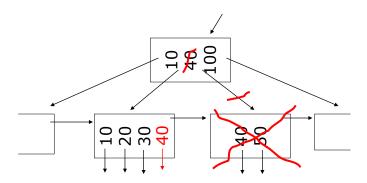

Deletion from B+tree

- (a) Simple case no example
- (b) Coalesce with neighbor (sibling)
- (c) Re-distribute keys
- (d) Cases (b) or (c) at non-leaf

(b) Coalesce with sibling

n=4

- Delete 50

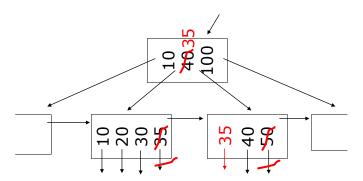

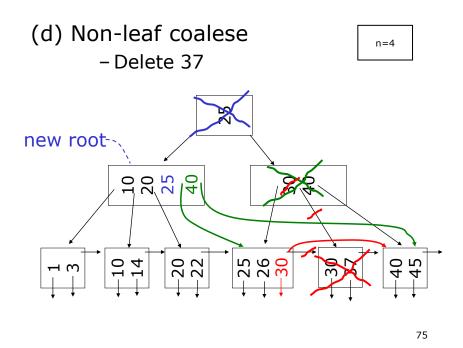

73

(c) Redistribute keys

n=4

– Delete 50

B+tree deletions in practice

- Often, coalescing is <u>not</u> implemented
 - Too hard and not worth it!

Least Recently Used

Is LRU a good policy for B+tree buffers?

Each block in the cache comes with a number according to when it was last used. If the cache is full, it will kick out the one that was most recently used.

This is why database systems take their own buffer and use their own caching policy and not rely on the operating system.

→ Of course not!

→ Should try to keep root in memory at all times

(and perhaps some nodes from second level)

All of the levels except for the last level are stored in cache

When the algorithm comes into conflict with the operating system, algorithm says I want to take my own buffer and I will have my own caching policy

77

Hardware+ indexing problem:

For B+tree, how large should *n* be?

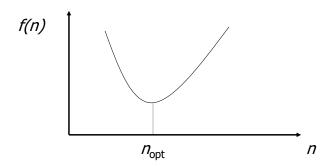

n is number of keys / node

Assumptions

- You have the right to set the block size for the disk where a B-tree will reside.
- Compute the optimum page size n assuming that
 - The items are 4 bytes long and the pointers are also 4 bytes long.
 - Time to read a node from disk is 12+.003n
 - Time to process a block in memory is unimportant
 - B+tree is full (I.e., every page has the maximum number of items and pointers

f(n) = time to find a record

Answer should be $n_{opt} = "few hundred"$

 $\mbox{$^{\sc b}$}$ What happens to $n_{\rm opt}$ as

- Disk gets faster?
- CPU get faster?

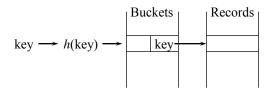

81

Outline/summary

- Conventional Indexes
 - Sparse vs. dense
 - Primary vs. secondary
- B+ trees main caching strategy
- Hashing schemes --> Next
- Bitmap indices

Hashing

- hash function h(key) returns address of bucket
- if the keys for a specific hash value do not fit into one page the bucket is a linked list of pages

hash functions should be spreading evenly across the buckets

Example hash function

- Key = $x_1 x_2 ... x_n'$ n byte character string
- Have b buckets
- h: add x₁ + x₂ + x_n
 - compute sum modulo b

- ☑ This may not be best function ...
- Read Knuth Vol. 3 if you really need to select a good function.

function:

Good hash

Expected number of keys/bucket is the same for all buckets

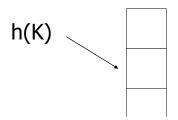

85

Within a bucket:

- Do we keep keys sorted?
 - Yes, if CPU time critical & Inserts/Deletes not too frequent

Need the hash structure to increase smoothly as the data grows when you find a big bucket isn't big enough

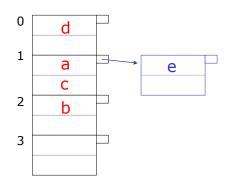

Next: example to illustrate inserts, overflows, deletes

87

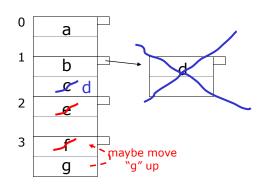

EXAMPLE 2 records/bucket

INSERT: h(a) = 1 h(b) = 2 h(c) = 1 h(d) = 0

EXAMPLE: deletion

89

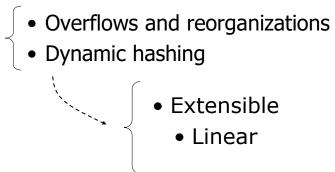

Rule of thumb:

 Try to keep space utilization between 50% and 80%

Utilization = <u># keys used</u> total # keys that fit

- If < 50%, wasting space

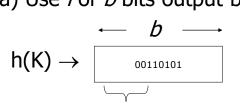

How do we cope with growth?

91

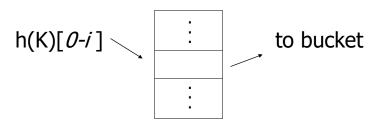

Extensible hashing: two ideas

(a) Use *i* of *b* bits output by hash function

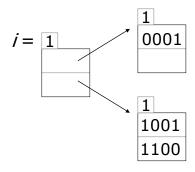

use $i \rightarrow$ grows over time....

(b) Use directory

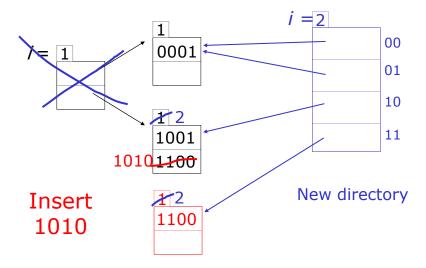

93

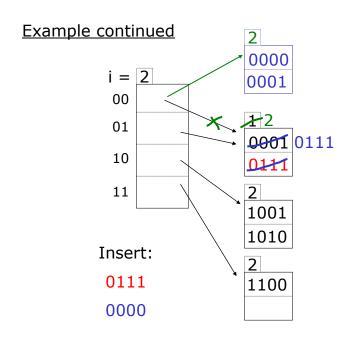

Example: h(k) is 4 bits; 2 keys/bucket

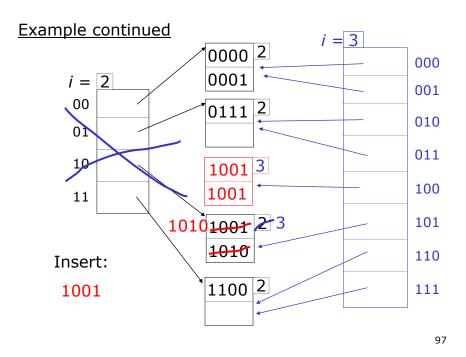

"slide" conventions: slide shows h(k), while actual directory has key+pointer

Example: h(k) is 4 bits; 2 keys/bucket

Extensible hashing: deletion

- No merging of blocks
- Merge blocks and cut directory if possible (Reverse insert procedure)

Deletion example:

Run thru insert example in reverse!

99

Summary

Extensible hashing

- + Can handle growing files
 - with less wasted space
 - with no full reorganizations
- Indirection

(Not bad if directory in memory)

Directory doubles in size

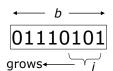

(Now it fits, now it does not)

Linear hashing

Another dynamic hashing scheme

Two ideas:

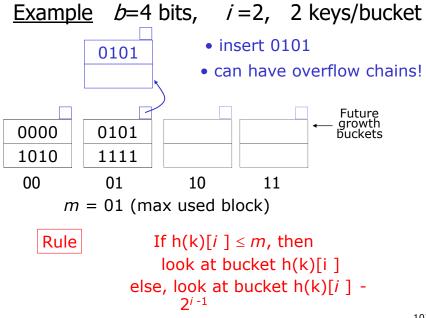

(a) Use *i* low order bits of hash

(b) File grows linearly

101

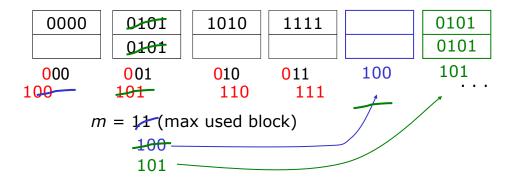

Example b=4 bits, i=2, 2 keys/bucket 0000 0101 1010 1111 00 01 10 11 m=01 (max used block)

103

Example Continued: How to grow beyond this?

11-

Keep track of: #used slots (incl. overflow) = U
 #total slots in primary buckets

equiv, <u>#(indexed key ptr pairs)</u>
#total slots in primary buckets

If U > threshold then increase m
 (and i, when m reaches 2ⁱ)

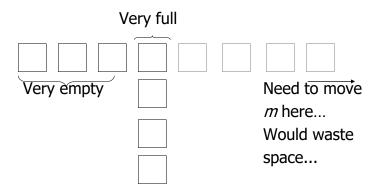

105

Summary

Linear Hashing

- Can handle growing files
 - with less wasted space
 - with no full reorganizations
- No indirection like extensible hashing
- Can still have overflow chains

Example: BAD CASE

107

Summary

Hashing

- ____- How it works
 - Dynamic hashing
 - Extensible
 - Linear

Next:

- Indexing vs Hashing
- Index definition in SQL
- Multiple key access

109

Indexing vs Hashing

Hashing good for probes given key
 e.g., SELECT ...
 FROM R
 WHERE R.A = 5

Indexing vs Hashing

• INDEXING (Including B Trees) good for Range Searches:

111

Index definition in SQL

- Create index name on rel (attr)
- Create unique index name on rel (attr)

---- defines candidate key

• <u>Drop</u> INDEX name

Note CANNOT SPECIFY TYPE OF INDEX

(e.g. B-tree, Hashing, ...)

OR PARAMETERS

(e.g. Load Factor, Size of Hash,...)

... at least in SQL...

113

Note ATTRIBUTE LIST \Rightarrow MULTIKEY INDEX (next) e.g., <u>CREATE INDEX</u> foo <u>ON</u> R(A,B,C)

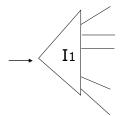

Multi-key Index

Motivation: Find records where DEPT = "Toy" AND SAL > 50k

115

Strategy I:

- Use one index, say Dept.
- Get all Dept = "Toy" records and check their salary

Strategy II:

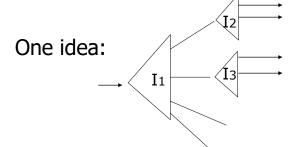

• Use 2 Indexes; Manipulate Pointers

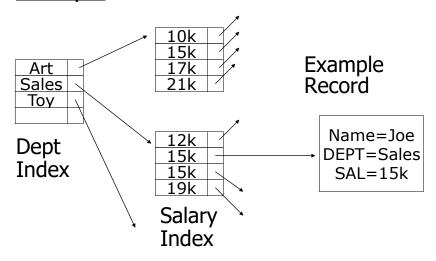

117

Strategy III:

• Multiple Key Index

Example

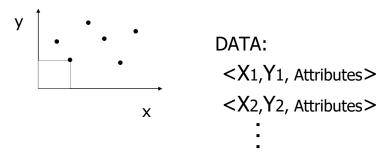

119

For which queries is this index good?

- \square Find RECs Dept = "Sales" \wedge SAL=20k
- □ Find RECs Dept = "Sales" \wedge SAL \geq 20k
- ☐ Find RECs Dept = "Sales"
- \Box Find RECs SAL = 20k

Interesting application:

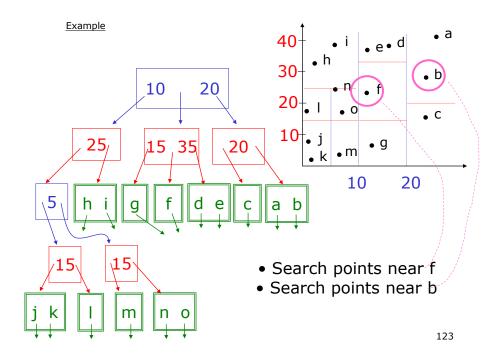

• Geographic Data

121

Queries:

- What city is at <Xi,Yi>?
- What is within 5 miles from <Xi,Yi>?
- Which is closest point to <Xi,Yi>?

Queries

- Find points with Yi > 20
- Find points with Xi < 5
- Find points "close" to i = <12,38>
- Find points "close" to $b = \langle 7,24 \rangle$

- Many types of geographic index structures have been suggested
 - Quad Trees
 - R Trees

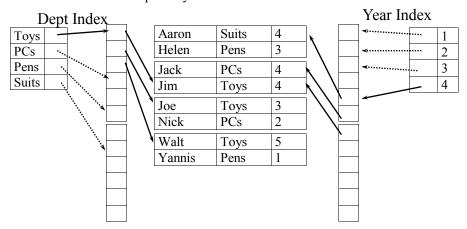

125

Outline/summary

- Conventional Indexes
 - Sparse vs. dense
 - Primary vs. secondary
- B+ trees
- Hashing schemes
- Bitmap indices --> Next

Revisit: Processing queries without accessing records until last step

Find employees of the Toys dept with 4 years in the company SELECT Name FROM Employee WHERE Dept="Toys" AND Year=4

Bitmap indices: Alternate structure, heavily used in OLAP

Assume the tuples of the Employees table are ordered.

Conceptually only!

D 4 I 1				
Dept Index				
Toys	00011010			
PCs	00100100			
Pens	01000001			
Suits	10000000			
	·			

Aaron	Suits	4
Helen	Pens	3
Jack	PCs	4
Jim	Toys	4
Joe	Toys	3
Nick	PCs	2
Walt	Toys	1
Yannis	Pens	1
		

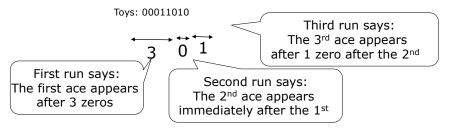

T 7	T 1	
Vaar	Index	,
i Cai	\mathbf{H}	L

00000011	1
00000100	2
01001000	3
10110000	4

- + Find even more quickly intersections and unions (e.g., Dept="Toys" AND Year=4)
- ? Seems it needs too much space -> We'll do compression
- ? How do we deal with insertions and deletions -> Easier than you think

Compression, with Run-Length Encoding

- Naive solution needs *mn* bits, where *m* is #distinct values and *n* is #tuples
- But there is just *n* 1's=> let's utilize this
- Encode sequence of **runs** (e.g. [3,0,1])

129

Byte-Aligned Run Length Encoding

Next key intuition: Spend fewer bits for smaller numbers

Consider the run **5, 200, 17**In binary it is **101, 11000100, 10001**

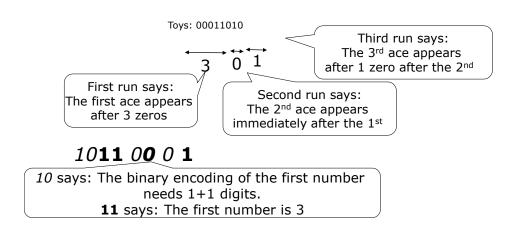

A binary number of up to 7 bits => 1 byte A binary number of up to 14 bits => 2 bytes

. . .

Use the first bit of each byte to denote if it is the last one of a number

00000101, 10000001, 01000100, 00010001 130

Bit-aligned 2nlog *m* Compression (simple version)

2nlog m compression

• Example

• Pens: 01000001

• Sequence [1,5]

• Encoding: *0***1***110***101**

Insertions and deletions & miscellaneous engineering

- Assume tuples are inserted in order
- Deletions: Do nothing
- Insertions: If tuple t with value v is inserted, add one more run in v's sequence (compact bitmap)

133

Summing Up...

We discussed how the database stores data + basic algorithms

- Sorting
- Indexing

How are they used in query processing?

Query Processing Notes

What happens when a query is processed and how to find out

Query Processing

- The query processor turns user queries and data modification commands into a query plan - a sequence of operations (or algorithm) on the database
 - from high level queries to low level commands
- Decisions taken by the query processor
 - Which of the algebraically equivalent forms of a query will lead to the most efficient algorithm?
 - For each algebraic operator what algorithm should we use to run the operator?
 - How should the operators pass data from one to the other? (eg, main memory buffers, disk buffers)

The differences between good plans and plans can be huge Example

Select B,D

From R,S

Where R.A = "c" \wedge S.E = 2 \wedge R.C=S.C

How do we execute query eventually?

One idea

- Scan relations
- Do Cartesian product

(literally produce all combinations of FROM clause tuples)

- Select tuples (WHERE)
- Do projection (SELECT)

	S.E
ζ	2
7	2
ζ (2
5	x y

Relational Plan:

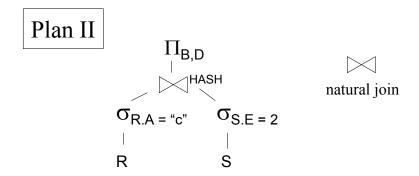

$$\underline{OR:}\Pi_{B,D}^{\mathsf{FLY}}[\,\sigma_{R.A=\text{``c''}\land\,S.E=2\,\land\,R.C\,=\,S.C}^{\mathsf{FLY}}\,(R^{\mathsf{SCAN}}\!X\,S^{\mathsf{SCAN}}\!)]$$

"FLY" and "SCAN" are the defaults

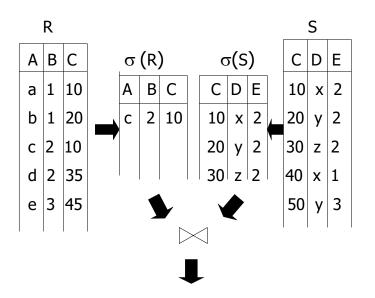

Ex: Plan I

$$\Pi_{\mathsf{B},\mathsf{D}}$$
 \mid $\sigma_{\mathsf{R}.\mathsf{A}= ext{`c''}\wedge\ \mathsf{S}.\mathsf{E}=2\ \wedge\ \mathsf{R}.\mathsf{C}=\mathsf{S}.\mathsf{C}}$ \mid X S

Another idea:

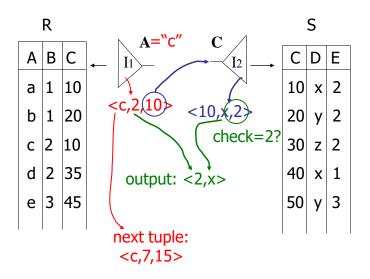

Scan R and S, perform on the fly selections, do join using a hash structure, project

Plan III

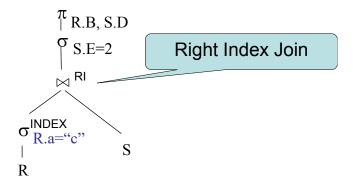

Use R.A and S.C Indexes

- (1) Use R.A index to select R tuples with R.A = "c"
- (2) For each R.C value found, use S.C index to find matching join tuples
- (3) Eliminate join tuples S.E \neq 2
- (4) Project B,D attributes

You don't know which is better, the hash join or the index join without knowing the statistics of the plan

Algebraic Form of Plan

From Query To Optimal Plan

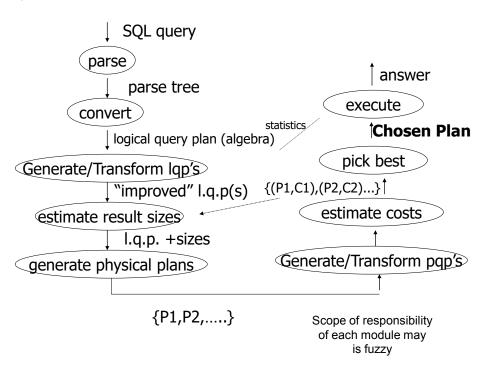

- Complex process
- Algebra-based logical and physical plans
- Transformations
- Evaluation of multiple alternatives

Issues in Query Processing and Optimization

- Generate Plans
 - employ efficient execution primitives for computing relational algebra operations
 - systematically transform expressions to achieve more efficient combinations of operators
- Estimate Cost of Generated Plans
 - Statistics, which are reported

Get rid of plans that get rid of massive intermediate results

Logical Query Plan

Difference between a bags of tuples and a set is that a bad can have duplicates

Algebraic Operators: A Bag version Tables are Bags of Tuples

- Union of R and S: a tuple t is in the result as many times as the sum of the number of times it is in R plus the times it is in S
- Intersection of R and S: a tuple t is in the result the minimum of the number of times it is in R and S
- Difference of R and S: a tuple t is in the result the number of times it is in R minus the number of times it is in S
- $\delta(R)$ converts the bag R into a set This is the equivalent of a distinct SQL's R UNION S is really $\delta(R \cup S)$
- **Example:** Let *R*={*A*,*B*,*B*} and *S*={*C*,*A*,*B*,*C*}.Describe the union, intersection and difference...

union, intersec

Union: AAA, BBB, C Intersection: A, B, C

Extended Projection

- project π_A , A is attribute list
 - The attribute list may include $x \rightarrow y$ in the list A to indicate that the attribute x is renamed to y
 - Arithmetic, string operators and scalar functions on attributes are allowed. For example,
 - $a+b\rightarrow x$ means that the sum of a and b is renamed into x.
 - clld→y concatenates the result of c and d into a new attribute named y
- The result is computed by considering each tuple in turn and constructing a new tuple by picking the attributes names in A and applying renamings and arithmetic and string operators
- Example:

Products and Joins

- Product of R and S (R×S):
 - If an attribute named a is found in both schemas then rename one column into R.a and the other into S.a
 - If a tuple r is found n times in R and a tuple s is found m times in S then the product contains nm instances of the tuple rs
- Joins

equality of common attributes

- Natural Join $R \bowtie S = \pi_A \sigma_C(R \times S)$ where
 - C is a condition that equates all common attributes
 - A is the concatenated list of attributes of R and S with no duplicates
 - · you may view tha above as a rewriting rule
- Theta Join
 - · arbitrary condition involving multiple attributes

Theta Join: take the Cartesian product but keep only the tuples where the condition is satisfied

Grouping and Aggregation

- YGroupByList; aggrFn1 → attr1 ,...,aggrFnN → attrN
- Conceptually, grouping leads to nested tables and is immediately followed by functions that aggregate the nested table
- $\begin{tabular}{ll} \bullet & Example: $\gamma_{Dept; \ AVG(Salary)} \to $$ \\ AvgSal \ ,..., \ SUM(Salary) \to SalaryExp \end{tabular}$

Find the average salary for each department SELECT Dept, AVG(Salary) AS AvgSal, SUM(Salary) AS SalaryExp FROM Employee GROUP-BY Dept

Employe	Employee						
Name	Dept	Salary					
Joe	Toys	45					
Nick	PCs	50					
Jim	Toys	35					
Jack	PCs	40					

Dept		d Table Salary	
Toys	Joe Jim	45 35	
PCs	Nick Jack	50 40	

Dept	AvgSal	SalaryExp
Toys	40	80
PCs	45	90

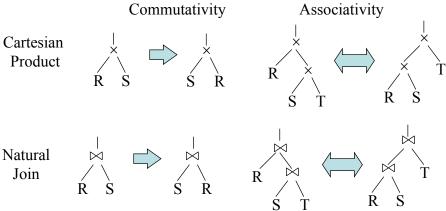

Sorting and Lists

- SQL and algebra results are ordered
- Could be non-deterministic or dictated by SQL ORDER BY, algebra τ
- T_{OrderByList}
- A result of an algebraic expression o(exp) is ordered if
 - If o is a т
 - If o retains ordering of exp and exp is ordered
 - · Unfortunately this depends on implementation of o
 - If o creates ordering
 - Consider that leaf of tree may be SCAN(R)

Relational algebra optimization

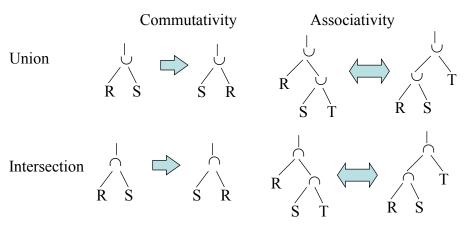

- Transformation rules (preserve equivalence)
- A quick tour

Algebraic Rewritings: Commutativity and Associativity

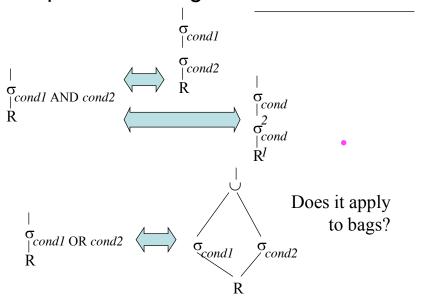

Question 1: Do the above hold for both sets and bags? **Question 2**: Do commutativity and associativity hold for arbitrary Theta Joins?

Algebraic Rewritings: Commutativity and Associativity (2)

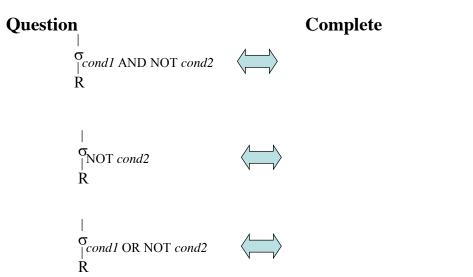

Question 1: Do the above hold for both sets and bags? **Question 2**: Is difference commutative and associative?

Algebraic Rewritings for Selection: Decomposition of Logical Connectives

Algebraic Rewritings for Selection: Decomposition of Negation

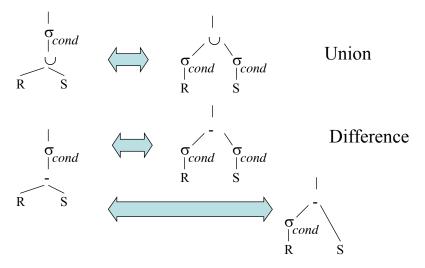

This is almost always beneficial

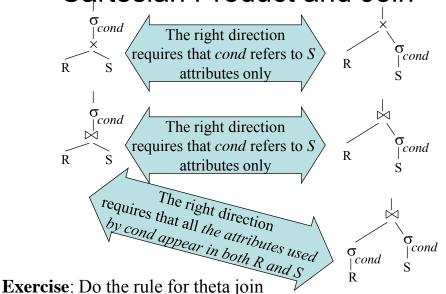

Apply the condition first, and then take the union

Pushing the Selection Thru Binary Operators: Union and Difference

Exercise: Do the rule for intersection

Pushing Selection thru Cartesian Product and Join

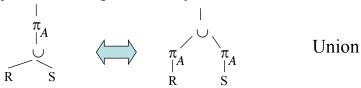

Rules: π,σ combined

Let x = subset of R attributes z = attributes in predicate P (subset of R attributes)

$$\pi_{x}[\sigma_{p(R)}] = \pi_{x}\{\sigma_{p}[\pi_{x}(R)]\}$$

Pushing Simple Projections Thru Binary Operators

A projection is simple if it only consists of an attribute list

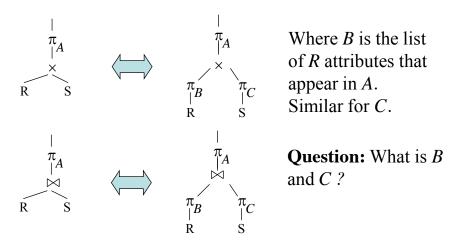

Question 1: Does the above hold for both bags and sets? **Question 2:** Can projection be pushed below

intersection and difference?

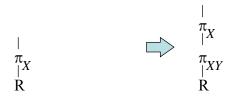

Answer for both bags and sets.

Pushing Simple Projections Thru Binary Operators: Join and Cartesian Product

Exercise: Write the rewriting rule that pushes projection below theta join.

Projection Decomposition

<u>Derived Rules:</u> $\sigma + \bowtie$ combined

More Rules can be Derived:

$$\sigma_{p \wedge q} (R \bowtie S) =$$

$$\sigma_{p \land q \land m} (R \bowtie S) =$$

$$\sigma_{pvq}(R \bowtie S) =$$

p only at R, q only at S, m at both R and S

--> Derivation for first one:

$$\sigma_{p \wedge q} (R \bowtie S) =$$

$$\sigma_p[\sigma_q(R\bowtie S)] =$$

$$\sigma_p[R\bowtie\sigma_q(S)] =$$

$$[\sigma_{\text{p}}\left(\text{R}\right)] \bowtie [\sigma_{\text{q}}\left(\text{S}\right)]$$

Which are always "good" transformations?

$$\Box$$
 $\sigma_{p1 \land p2}(R) \rightarrow \sigma_{p1}[\sigma_{p2}(R)]$

$$\Box \ \ \sigma_p \ (R \bowtie S) \rightarrow [\sigma_p \ (R)] \ \bowtie S$$

$$\square R \bowtie S \rightarrow S \bowtie R$$

$$\ \square \ \pi_{x}\left[\sigma_{p}\left(R\right)\right] \to \pi_{x}\left\{\sigma_{p}\left[\pi_{xz}\left(R\right)\right]\right\}$$

In textbook: more transformations

- Eliminate common sub-expressions
- · Other operations: duplicate elimination

Bottom line:

- No transformation is always good at the I.q.p level
- Usually good
 - early selections
 - elimination of cartesian products
 - elimination of redundant subexpressions
- Many transformations lead to "promising" plans
 - Commuting/rearranging joins
 - In practice too "combinatorially explosive" to be handled as rewriting of l.q.p.

Algorithms for Relational • Three primary techniques

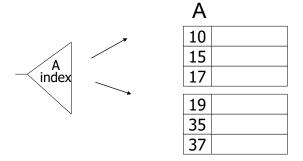

- - Sorting
 - Hashing
 - Indexing
- Three degrees of difficulty
 - data small enough to fit in memory
 - too large to fit in main memory but small enough to be handled by a "two-pass" algorithm two phase sort from earlier in the deck
 - so large that "two-pass" methods have to be generalized to "multi-pass" methods (quite unlikely nowadays)

The dominant cost of operators running on disk:

 Count # of disk blocks that must be read (or written) to execute query plan

Clustering index

Index that allows tuples to be read in an order that corresponds to a sort order

Clustering can radically change cost

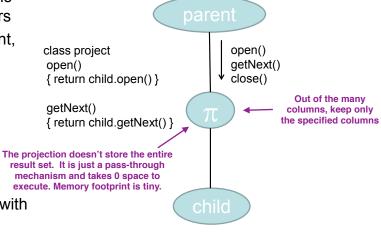

Clustered relation

R1 R2 R3 R4 R5 R5 R7 R8

Clustering index

Pipelining can radically change cost

- Interleaving of operations across multiple operators
- Smaller memory footprint, fewer object allocations
- Operators support:
 - open()
 - getNext()
 - close()
- Simple for unary
- Pipelined operation for binary discussed along with physical operators

This is known as the iterator model of execution. Mostly because of the getNext() clause. In the context of main memory dbs, it is criticized because in order to get ANY tuple, there are many function calls in a big plan...you may have to traverse many levels in order to produce anything.

Pipeline and iterative contrasted to the naive approach to get data from the child and send to parent.

Sort and Group By are blocking operators, which means that the operator can't return anything without getting the entire result set. You can make plans that are blocking and not blocking.

Example R1 R2 over common attribute C

First we will see main memory-based implementations

- <u>Iteration join</u> (conceptually without taking into account disk block issues)
- For each tuple of left argument, re-scan the right argument

for each $r \in R1$ do for each $s \in R2$ do if r.C = s.C then output r,s pair

Also called "nested loop join" in some databases (eg Postgres)

this is bad because it is quadratic not linear.

- Join with index (Conceptually)
 - alike iteration join but right relation accessed with index

For each $r \in R1$ do [$X \leftarrow \text{index} (R2, C, r.C)$ for each $s \in X$ do output r,s pair]

Note: X ← index(rel, attr, value)
then X = set of rel tuples with attr = value

This is how an index is useful in join queries.

Merge join (conceptually)

(1) if R1 and R2 not sorted, sort them (2) $i \leftarrow 1$; $j \leftarrow 1$;

While (i
$$\leq$$
 T(R1)) \wedge (j \leq T(R2)) do if R1{ i }.C = R2{ j }.C then outputTuples else if R1{ i }.C > R2{ j }.C then j \leftarrow j+1 else if R1{ i }.C < R2{ j }.C then i \leftarrow i+1

Procedure Output-Tuples

While (R1{ i }.C = R2{ j }.C)
$$\land$$
 (i \le T(R1)) do [jj \leftarrow j; while (R1{ i }.C = R2{ jj }.C) \land (jj \le T(R2)) do [output pair R1{ i }, R2{ jj }; jj \leftarrow jj+1] i \leftarrow i+1]

Example

i	R1{i}.C	R2{j}.C	j_
1	10	5	1
2	20	20	2
3	20	20	3
4	30	30	4
5	40	30	5
		50	6
		52	7

- Hash join, hashing both sides (conceptual)
 - Hash function h, range $0 \rightarrow k$
 - Buckets for R1: G0, G1, ... Gk
 - Buckets for R2: H0, H1, ... HkAlgorithm
 - (1) Hash R1 tuples into G buckets
 - (2) Hash R2 tuples into H buckets
 - (3) For i = 0 to k do match tuples in Gi, Hi buckets

Simple example hash: even/odd

R1	R2		Buckets					
2	5	Even	2 4 8	4 12 8 14				
4	4		R1	R2				
3	12	Odd:	3 5 9	5 3 13 11				
5	3		333	3 3 13 11				
8	13							
9	8							
	11							
	14							

Variation: Hash one side only

Algorithm

- (1) Hash R1 tuples into G buckets
- (2) For each tuple r2 or R2 find i=hash(r2) match r2 with tuples in Gi

What's the benefit in hashing both sides? Wait till we discuss hash joins on secondary storage...

Disk-oriented Cost Model

- There are *M* main memory buffers.
 - Each buffer has the size of a disk block
- The input relation is read one block at a time.
- · The cost is the number of blocks read.
- (Applicable to Hard Disks:) If *B* consecutive blocks are read the cost is *B/d*.

 You can tune d in postgresql... discount factor
- The output buffers are not part of the M buffers mentioned above.
 - Pipelining allows the output buffers of an operator to be the input of the next one.
 - We do not count the cost of writing the output.

Notation

- *B*(*R*) = number of blocks that *R* occupies
- T(R) = number of tuples of R
- $V(R,[a_1, a_2,..., a_n])$ = number of distinct tuples in the projection of R on $a_1, a_2,..., a_n$

One-Pass Main Memory Algorithms for Unary Operators

- Assumption: Enough memory to keep the relation
- · Projection and selection:
 - Scan the input relation R and apply operator one tuple at a time
 - Incremental cost of "on the fly" operators is 0
- · Duplicate elimination and aggregation
 - create one entry for each group and compute the aggregated value of the group
 - it becomes hard to assume that CPU cost is negligible
 - · main memory data structures are needed

One-Pass Nested Loop Join Only one of the two arguments have to be stored in main memory

- Assume B(R) is less than M I can have the entire R in memory
- Tuples of R should be stored in an efficient lookup structure
- Exercise: Find the cost of the algorithm below

```
for each block Br of R do
  store tuples of Br in main memory
for each each block Bs of S do
  for each tuple s of Bs
    join tuples of s with matching tuples of R
```

A variation where the inner side is organized into a hash (hash join in some databases)

```
for each block Br of R do
  store tuples of Br in main memory
               hash buckets G1,..., Gn
for each each block Bs of S do
  for each tuple s of Bs
     find h=hash(s)
     join s with matching tuples in Gh
```

Generalization of Nested-Loops

```
for each chunk of M-1 blocks Br of R do
  store tuples of Br in main memory
  for each each block Bs of S do
    for each tuple s of Bs
        join tuples of s with matching tuples of R
```

Exercise: Compute cost

Simple Sort-Merge Join

- Assume natural join on C
- Sort R on C using the twophase multiway merge sort
 - if not already sorted
- Sort S on C
- Merge (opposite side)
 - assume two pointers Pr,Ps to tuples on disk, initially pointing a the start
 - sets R', S' in memory
- Remarks:
 - Very low average memory requirement during merging (but no guarantee on how much is needed)
 - Cost:

```
while Pr!=EOF and Ps!=EOF
  if *Pr[C] == *Ps[C]
    do_cart_prod(Pr,Ps)
  else if *Pr[C] > *Ps[C]
    Ps++
  else if *Ps[C] > *Pr[C]
    Pr++

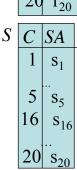

function do_cart_prod(Pr,Ps)
  val=*Pr[C]
  while *Pr[C]==val
    store tuple *Pr in set R'
  while *Ps[C]==val
    store tuple *Ps in set S';
  output cartesian product
    of R' and S'
```

Efficient Sort-Merge Join

- Idea: Save two disk I/O's per block by combining the second pass of sorting with the ``merge".
- Step 1: Create sorted sublists of size M for R and S
- Step 2: Bring the first block of each sublist to a buffer
 - assume no more than *M* sublists in all
- Step 3:Repeatedly find the least C value c among the first tuples of each sublist. Identify all tuples with join value c and join them.
 - When a buffer has no more tuple that has not already been considered load another block into this buffer.

Efficient Sort-Merge Join _ Example

 $\begin{array}{c|cccc}
R & C & RA \\
\hline
1 & r_1 \\
2 & r_2 \\
3 & r_3 \\
... \\
20 & r_{20}
\end{array}$

Assume that after first phase of multiway sort we get 4 sublists, 2 for *R* and 2 for *S*.

Also assume that each block contains two tuples.

										18
	1	2	4	5	6	9	12	15	19	20
'.										

Sort and Merge Join are typically separate operators

- Modularity
 - The sorting needed by join is no different than the sorting needed by ORDER BY
- May be only one side or no side needs sorting

Two-Pass Hash-Based Algorithms

- General Idea: Hash the tuples of the input arguments in such a way that all tuples that must be considered together will have hashed to the same hash value.
 - If there are M buffers pick M-1 as the number of hash buckets
- Example: Duplicate Elimination
 - Phase 1: Hash each tuple of each input block into one of the M-1 bucket/buffers. When a buffer fills save to disk.
 - Phase 2: For each bucket:
 - · load the bucket in main memory,
 - · treat the bucket as a small relation and eliminate duplicates
 - · save the bucket back to disk.
 - Catch: Each bucket has to be less than M.
 - Cost:

Hash-Join Algorithms

- Assuming natural join, use a hash function that
 - is the same for both input arguments R and S
 - uses only the join attributes
- Phase 1: Hash each tuple of R into one of the M-1 buckets R_i and similar each tuple of S into one of S_i
- Phase 2: For i=1...M-1
 - load R_i and S_i in memory
 - join them and save result to disk
- Question: What is the maximum size of buckets?
- Question: Does hashing maintain sorting?

Index-Based Join: The Simplest Version

Assume that we do natural join of R(A,B) and S(B,C) and there's an index on S

```
for each Br in R do
  for each tuple r of Br with B value b
    use index of S to find
       tuples {s<sub>1</sub>, s<sub>2</sub>,...,s<sub>n</sub>} of S with B=b
    output {rs<sub>1</sub>, rs<sub>2</sub>,...,rs<sub>n</sub>}
```

Cost: Assuming *R* is clustered and non-sorted and the index on *S* is clustered on *B* then

B(R)+T(R)B(S)/V(S,B) + some more for reading index

Question: What is the cost if *R* is sorted?

B(R) + T(R)(1+T(S)/(k*V(S,B)))

I can fit k numbers in a block

Reading the plan that was chosen by the database (EXPLAIN)

EXPLAIN SELECT s.pid, s.first_name, s.last_name, e.credits FROM students s, enrollment e WHERE s.id = e.student AND e.class = 1;

Notes on physical operators of Postgres and other databases

σ_c R turns into single operator

Sequential Scan with filter c

Seq Scan on R

Filter: (c)

Index Scan

Index Scan using <index> on R

Index Cond: (c)

201

Steps of joins, aggregations broken into fine granularity operators

- No sort-merge: Separate sort and merge
- Hash join has separate operation creating hash table and separate operation doing the looping

202

Sorting

- Sorting may be accomplished using index
 - Rarely wins 2-phase sort if table is not clustered and is much bigger than memory

203

- Estimating cost of query plan
- (1) Estimating size of results
- (2) Estimating run time (often reduces to #IOs)

Both estimates can go very wrong!

Output pane

How does the database estimate query run time?

UNDERTY PLAN text

Hash Join (cost=1.07..2.17 ows=3 width=100)

Hash Cond: (c-student = s.id)

Seq Scan on enrollment e (cost=0.00..1.06 rows=3 width=8)

Filter: (class = 1)

Seq Scan on students s (cost=0.00..1.03 rows=3 width=100)

Seq Scan on students s (cost=0.00..1.03 rows=3 width=100)

Estimating result size

- Keep statistics for relation R
 - T(R): # tuples in R
 - S(R): # of bytes in each R tuple
 - B(R): # of blocks to hold all R tuples
 - V(R, A): # distinct values in R for attribute A

Example

R

Α	В	С	D
cat	1	10	a
cat	1	20	b
dog	1	30	а
dog	1	40	С
bat	1	50	d

A: 20 byte string

B: 4 byte integer

C: 8 byte date

D: 5 byte string

$$T(R) = 5$$
 $S(R) = 37$

$$V(R,A) = 3$$

$$V(R,A) = 3$$
 $V(R,C) = 5$

$$V(R,B) = 1$$
 $V(R,D) = 4$

$$V(R,D) = 4$$

Size estimates for $W = R1 \times R2$

$$T(W) = T(R1) \times T(R2)$$

$$S(W) = S(R1) + S(R2)$$

Size estimate for W = $\sigma_{Z=val}$ (R)

$$S(W) = S(R)$$

$$T(W) = ?$$

Example

$$W = \sigma_{z=val}(R) \quad T(W) = \frac{T(R)}{V(R,Z)}$$

What about
$$W = \sigma_{z \ge val}(R)$$
 ?

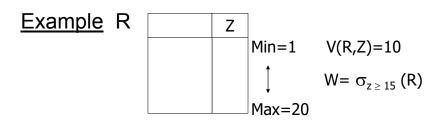

$$T(W) = ?$$

- Solution # 1:
 T(W) = T(R)/2

Solution #2:

$$T(W) = T(R)/3$$

• Solution # 3: Estimate values in range

$$f = 20-15+1 = 6$$
 (fraction of range)
20-1+1 20

$$T(W) = f \times T(R)$$

Equivalently:

$$f \times V(R,Z) = fraction of distinct values$$

$$T(W) = [f \times V(Z,R)] \times T(R) = f \times T(R)$$

$$V(Z,R)$$

Size estimate for W = R1 ⋈ R2

Let x = attributes of R1 y = attributes of R2

Case 1

 $X \cap Y = \emptyset$

Same as R1 x R2

trivial join: where their is no commonality

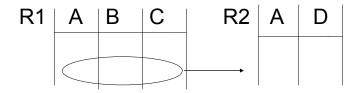

Case 2 $W = R1 \bowtie R2$ $X \cap Y = A$

Joins are almost always that there's a primary key on one table is a foreighn key of another table.

Assumption:

 Π_A R1 \subseteq Π_A R2 \Rightarrow Every A value in R1 is in R2 (typically A of R1 is foreign key of the primary key of A of R2) Π_A R2 \subseteq Π_A R1 \Rightarrow Every A value in R2 is in R1 "containment of value sets" (justified by primary key – foreign key relationship)

Computing T(W) when A of R1 is the foreign key $\Pi_A R1 \subseteq \Pi_A R2$

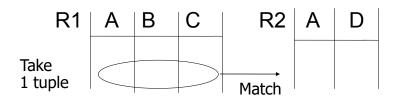

1 tuple of R1 matches with exactly 1 tuple of R2

so
$$T(W) = T(R1)$$

Another way to approach when

$$\Pi_A R1 \subseteq \Pi_A R2$$

1 tuple matches with T(R2) tuples... V(R2,A)

so
$$T(W) = \frac{T(R2) \times T(R1)}{V(R2, A)}$$

•
$$V(R1,A) \le V(R2,A)$$
 $T(W) = T(R2) T(R1)$
 $V(R2,A)$

•
$$V(R2,A) \le V(R1,A)$$
 $T(W) = \frac{T(R2) T(R1)}{V(R1,A)}$

[A is common attribute]

In general
$$W = R1 \bowtie R2$$

$$T(W) = \frac{T(R2) T(R1)}{\max\{ V(R1,A), V(R2,A) \}}$$

Combining estimates on subexpressions: Value preservation

Value preservation may have to be pushed to a weird assumption (but there's logic behind it!)

Value Preservation assumption probabilistically assumes that the features are independent.

$$R(A, C)$$
 $S(A, B)$
 $T(R) = 10^3$ $T(S) = 10^2$
 $V(A, R) = 10^3$ $V(A, S) = 50$
 $V(C, R) = 10^2$

$$T(R \bowtie S) = 10^2$$

$$V(C, R \bowtie S) = 10^{2}$$

$$T(Result) = 1$$

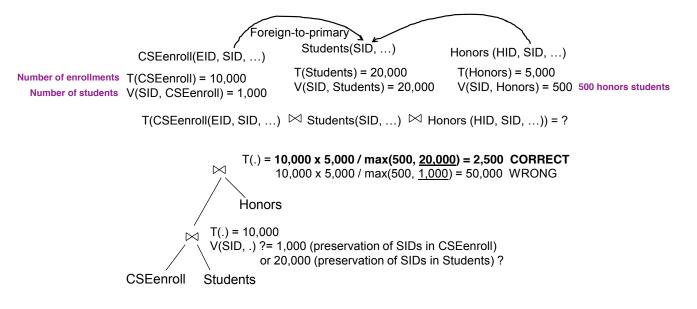

Ideally, the size estimation should not depend on which of the two equivalent formulas for Result one uses. However, to achieve this we may need to push the value preservation assumption to artificial intermediate estimates...

$$\begin{split} &T(\sigma_{c=1}R) = T(R) \ / \ V(C,\,R) = 10 \\ &V(A,\,\sigma_{c=1}R) = \textbf{10}^3 \\ &T(Result) = \\ &T(\sigma_{c=1}R) \ x \ T(S) \ / \ max(V(A\,,\,\sigma_{c=1}R),\,V(A,\,S)) = 1 \end{split}$$

We had to extend value preservation to the weird assumption that attribute A has more values than the number of tuples in R. In this way the number of S tuples matching an R tuple stays steady

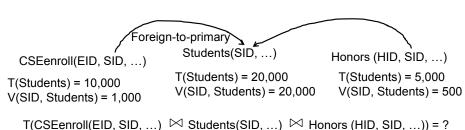

Value preservation of join attribute

??consider join CSE join honors without student honors

If in doubt, think in terms of probabilities and matching records

- A SID of Student appears in CSEEnroll with probability 1000/20000
 - i.e., 5% of students are enrolled in CSE
- A SID of Student appears in Honors with probability 500/20000
 - i.e., 2.5% of students are honors students
- => An SID of Student appears in the join result with probability 5% x 2.5%
- On the average, each SID of CSEEnroll appears in 10,000/1,000 tuples
 - i.e., each CSE-enrolled student has 10 enrollments
- On the average, each SID of Honors appears in 5,000/500 tuples
 - i.e., each honors' student has 10 honors
- ⇒Each Student SID that is in both Honors and CSEEnroll is in 10x10 result tuples
- \Rightarrow T(result) = 20,000 x 5% x 2.5% x 10 x 10 = 2,500 tuples

Plan Enumeration: Yet another source of suboptimalities

Not all possible equivalent plans are generated

- Possible rewritings may not happen
- Join sequences of n tables lead to #plans that is exponential in n
 - Eg, Postgres comes with a default exhaustive search for up to 12 joins

Morale: The plan you have in mind have not been considered

Arranging the Join Order: the Wong-Youssefi algorithm (INGRES)

Sample TPC-H Schema

Nation(NationKey, NName)
Customer(CustKey, CName, NationKey)
Order(OrderKey, CustKey, Status)
Lineitem(OrderKey, PartKey, Quantity)
Product(SuppKey, PartKey, PName)
Supplier(SuppKey, SName)

SELECT SName

FROM Nation, Customer, Order, LineItem, Product, Supplier WHERE Nation.NationKey = Cuctomer.NationKey

AND Customer.CustKey = Order.CustKey AND Order.OrderKey=LineItem.OrderKey AND LineItem.PartKey= Product.Partkey AND Product.Suppkey = Supplier.SuppKey

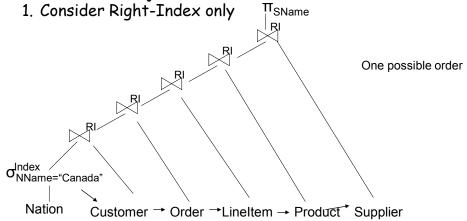

AND NName = "Canada"

Find the names of suppliers that sell a product that appears in a line item of an order made by a customer who is in Canada

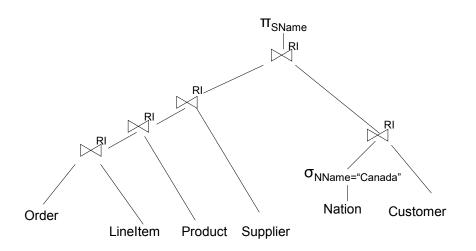

Challenges with Large Natural Join Expressions

For simplicity, assume that in the query

- 1. All joins are natural
- 2. whenever two tables of the FROM clause have common attributes we join on them

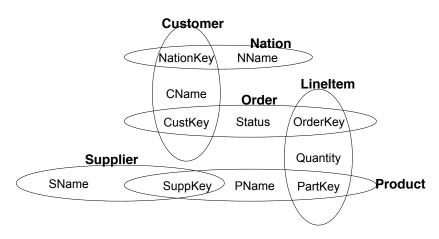

Multiple Possible Orders

Wong-Yussefi algorithm assumptions and objectives

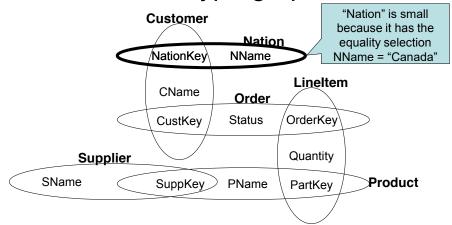

- Assumption 1 (weak): Indexes on all join attributes (keys and foreign keys)
- Assumption 2 (strong): At least one selection creates a small relation
 - A join with a small relation results in a small relation
- Objective: Create sequence of indexbased joins such that all intermediate results are small

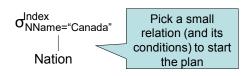

Hypergraphs

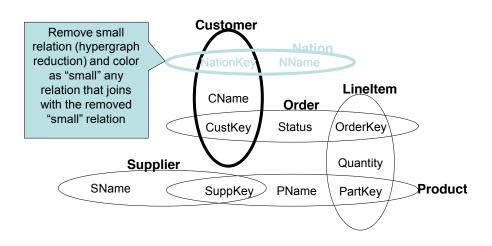

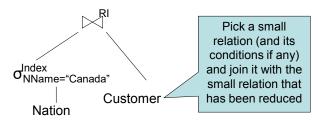

- relation hyperedges
 - · two hyperedges for same relation are possible
- · each node is an attribute
- · can extend for non-natural equality joins by merging nodes

Small Relations/Hypergraph Reduction

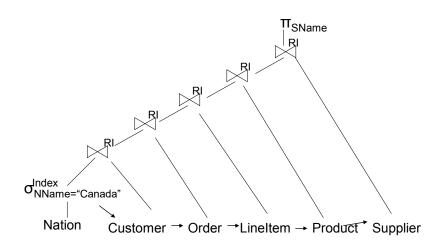

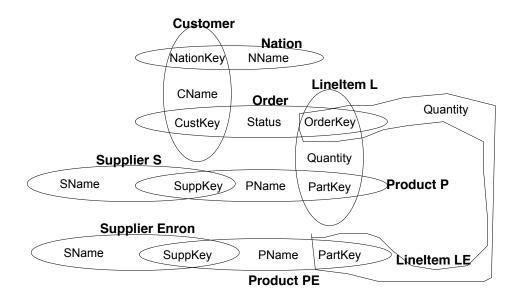

After a bunch of steps...

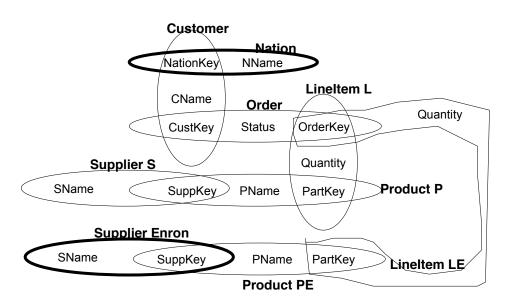

Multiple Instances of Each Relation

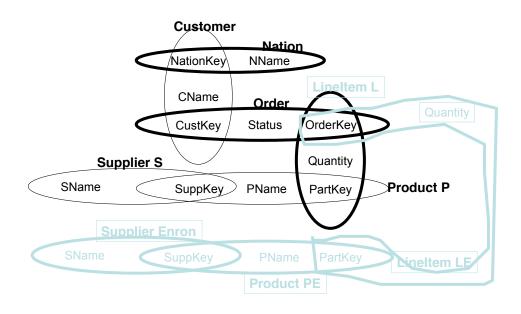

SELECT S.SName Find the FROM Nation, Customer, Order, LineItem L, Product P, Supplier S, names of LineItem LE, Product PE, Supplier Enron suppliers WHERE Nation.NationKey = Cuctomer.NationKey whose AND Customer.CustKey = Order.CustKey products AND Order.OrderKey=L.OrderKey appear in an AND L.PartKey= P.Partkey order made by AND P.Suppkey = S.SuppKey a customer AND Order.OrderKey=LE.OrderKey who is in AND LE.PartKey= PE.Partkey Cayman AND PE.Suppkey = Enron.SuppKey Islands and an AND Enron. Sname = "Enron" Enron product AND NName = "Cayman" appears in the same order

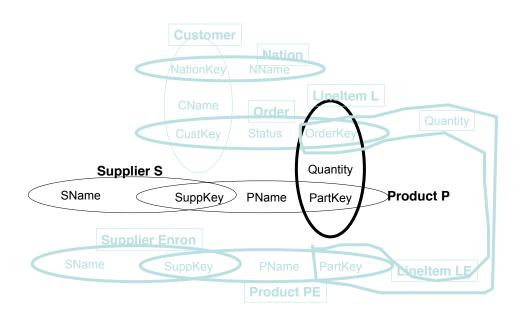

Multiple Instances of Each Relation

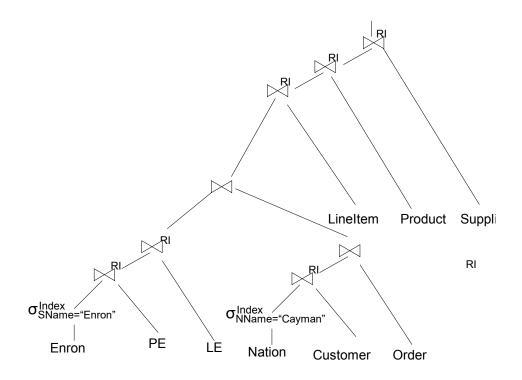

Multiple choices are possible

The basic dynamic programming approach to enumerating plans

for each sub-expression

 $op(e_1 e_2 \dots e_n)$ of a logical plan

- (recursively) compute the best plan and cost for each subexpression e_i
- for each physical operator op^p implementing op
 - evaluate the cost of computing op using op^p and the best plan for each subexpression e_i
 - (for faster search) memo the best op^p

Local suboptimality of basic approach and the Selinger improvement

- Basic dynamic programming may lead to (globally) suboptimal solutions
- Reason: A suboptimal plan for e_1 may lead to the optimal plan for $op(e_1 e_2 ... e_n)$
 - Eg, consider $e_1 \searrow e_2$ and
 - assume that the optimal computation of e_1 produces unsorted result

 - It could have paid off to consider the suboptimal computation of e₁ that produces result sorted on A
- Selinger improvement: memo also any plan (that computes a subexpression) and produces an order that may be of use to ancestor operators

Using dynamic programming to optimize a join expression

- Goal: Decide the join order and join methods
- Initiate with n-ary join $C(e_1 e_2 \dots e_n)$, where c involves only join conditions
- Bottom up: consider 2-way non-trivial joins, then 3-way non-trivial joins etc
 - "non trivial" -> no cartesian product

Summary

We learned

- how a database processes a query
- · how to read the plan the database chose
 - Including size and cost estimates

Back to action:

- Choosing Indices, with our knowledge of cost with and without indices
- What if the database cannot find the best plan?
